

ZVAKTHOR — Deterministic Control for Autonomous Trading Agents

An algorithmic execution platform for global financial markets that separates **intelligence** from **control**: specialist agents analyse markets independently, while an isolated Rust core validates every decision for risk and execution eligibility before any order reaches the market. Every decision — accepted or rejected — is recorded and replayable.

Non-custodial by design **Deterministic** kill-switch **Boundary**: Python intelligence / Rust governance

ARCHITECTURE — THREE LAYERS, ONE ENFORCED BOUNDARY

WHAT THE ARCHITECTURE ENFORCES

- **No unvalidated order** — validation is a precondition of execution, not a post-trade check.
- **Full decision lineage** — accepted and rejected decisions are both recorded and replayable.
- **Bounded authority** — explicit scope, validity and revocation, enforced at the authorisation boundary.
- **Reproducibility** — a decision is reproducible only from a versioned execution context.
- **Failure containment** — no valid-looking partial state; committed state survives process or node failure.

CUSTODY, STATUS, AND THE LAYER THAT DECIDES OUTCOMES

Non-custodial by design. The software is licensed and run by clients on their own broker accounts. Capital stays in the client's name, and the system never takes discretionary control.

Status. Core architecture and the first agent group are validated end to end in a demo environment. Remaining agents activate as their data infrastructure is funded. No live performance figures are published.

Research premise. Production evidence indicates agent behaviour is driven by interface and execution design, not model reasoning quality alone — the Operating-Layer Dominance Hypothesis. **IMPERION** applies the same governance discipline to automating AI system architecture decisions.
